1.1 Statistical Thermodynamics and Free Energy

1.2 Umbrella Sampling (US)

1.3 Adaptive Biasing Methods

Instead of dividing the reaction coordinate in several windows, with adaptive biasing methods the free energy can be estimated from one single simulation. For this purpose the systems dynamics are biased towards states corresponding to large values of the free energy along the transition coordinate via a history-dependent biasing potential. In contrast to other importance sampling strategies like umbrella sampling, this methods require no prior knowledge of the free-energy landscape at hand. Instead, the biasing potential automatically converges towards the free energy, enabling diffusive behavior along the transition coordinate.

There are multiple adaptive biasing methods available, only differing in the choice of bias. Methods based on metadynamics (metaD) disfavor already visited states by accumulating repulsive potentials along the reaction coordinate (section 1.3.1), while adaptive biasing force (ABF) methods compensate the mean force along the reaction coordinate to obtain uniform sampling (sections 1.3.2 and 1.3.3). Meta-eABF combines both complementary approaches to speed up the convergence of the free energy estimate (section 1.3.4).

In principle adaptive biasing methods only rely on the sampling of the canonical ensemble. One simple way to achieve this is using Langevin dynamics with sufficiently soft damping and small stochastic forces. A schematic procedure of adaptively biased Langevin dynamics is given in Algorithm 1.

Algorithm 1 Velocity Verlet integrator for adaptively biased Langevin dynamics with atomic masses \mathbf{M} , coordinates $\mathbf{x}(t)$, momenta $\mathbf{p}(t)$, potential $V(\mathbf{x}(t))$, forces $F(\mathbf{x}(t))$ and friction coefficient γ ,

while $t < t_{end}$ **do**

$\mathbf{p}(t + \frac{1}{2}\Delta t) \leftarrow \mathbf{p}(t) + \frac{1}{2}(F(\mathbf{x}(t))dt - \gamma\mathbf{M}^{-1}\mathbf{p}(t)dt + \sqrt{2\gamma\beta^{-1}}dW_t)$
/* Get momenta at half time step

$\mathbf{x}(t + \Delta t) \leftarrow \mathbf{x}(t) + \frac{2}{2+\gamma dt}\mathbf{M}^{-1}\mathbf{p}(t + \frac{1}{2}\Delta t)dt$
/* Propagate coordinates

$F(\mathbf{x}, t + \Delta t) \leftarrow -\nabla V(\mathbf{x}(t + \Delta t))$
/* get QM or MM forces $F(\mathbf{x}(t))$ for new coordinates

$F(\mathbf{x}, t + \Delta t) \leftarrow F(\mathbf{x}, t + \Delta t) + F^{bias}(\mathbf{x}, t + \Delta t)$
/* call adaptive biasing routine to update bias force

$\mathbf{p}(t + \Delta t) = \frac{2-\gamma dt}{2+\gamma dt}\mathbf{p}(t + \frac{1}{2}\Delta t) - \frac{1}{2}(F(\mathbf{x}(t + \Delta t))dt - \gamma\mathbf{M}^{-1}\mathbf{p}(t + \frac{1}{2}\Delta t)dt + \sqrt{2\gamma\beta^{-1}}dW)$
/* Get momenta at full time step

end while

1.3.1 Well-Tempered Metadynamics (WT-MetaD)

MetaD biases a systems dynamic towards undersampled regions along the reaction coordinate $\xi(\mathbf{x})$, by accumulating repulsive potentials in regions that have already been visited. The bias potential is typically build by a superposition of repulsive Gaussian kernels and can be written:^[1]

$$V^{metaD}(\xi, t) = \sum_{k < \frac{t}{\tau_G}} \tau_G \omega \exp\left(-\sum_{i=1}^{N_{dim}} \frac{1}{2\sigma_i^2} (\xi_i(\mathbf{x}) - \xi_i(\mathbf{x}, t_k))^2\right) \quad (1.1)$$

with deposition rate τ_G , Gaussian height $\omega = W/\tau_G$ and variance σ^2 as free input parameters. In practice $V^{metaD}(\xi, t)$ is stored on a grid and updated every τ_G time steps for computational efficiency. Over the course of a simulation the bias potential fills local minima along the reaction coordinate until the systems evolution finally resembles a Brownian motion along the flattened free energy surface. The converged bias potential provides an unbiased estimate of the underlying free energy surface

$$V^{metaD}(\xi, t \rightarrow \infty) = -A(\xi) + C \quad (1.2)$$

To avoid oscillation of V^{metaD} around the correct free energy, Well-Tempered metadynamics (WTM) introduces an additional scaling factor of the Gaussian height:^[2]

$$\omega(\xi, t) = \frac{W}{\tau_G} \exp\left(-\frac{V^{WTM}(\xi, t)}{k_B \Delta T}\right) \quad (1.3)$$

ensuring an decrease of ω over time and smooth convergence of the Well-Tempered bias potential $V^{WTM}(\xi, t)$. However, the new bias potential does not fully compensate the free energy surface, but can be controlled by parameter ΔT . For $T \rightarrow 0$ the bias is zero and ordinary MD is recovered, whereas the limit $\Delta T \rightarrow \infty$ corresponds to normal metaD. To obtain a unbiased free energy estimate from $V^{WTM}(\xi, t)$ it has to be scaled accordingly:

$$A(\xi) = -\frac{T + \Delta T}{\Delta T} V^{WTM}(\xi, t) \quad (1.4)$$

1.3.2 Adaptive Biasing Force Method (ABF)

The intuition behind ABF is, that adding a force $A'(\xi(\mathbf{x}))\nabla\xi(\mathbf{x})$ that exactly compensates the average of the original force $-\nabla V(\mathbf{x})$ along a given coordinate would result in uniform sampling along this coordinate.^[3] Historically, this idea emerged from thermodynamic integration (TI), where the free energy derivative is computed as the ensemble average of the instantaneous force, F , acting along a given reaction coordinate $\xi : \mathbb{R}^{3N} \rightarrow \mathbb{R}$:

$$\frac{dA}{d\xi} = -\langle F \rangle_\xi \quad (1.5)$$

and the free energy is calculated as the integral over this force.^[4,5] In practice, as one has no prior knowledge of the free energy derivative, ABF uses an on-the-fly estimate of the mean force acting along the reaction coordinate. For this purpose the transition coordinate ξ , connecting two end points, is divided in M equally spaced bins. The approximation of the bias force $\bar{F}(N_{Step}, k)$ in bin k is than the average of all collected force samples:^[3]

$$\bar{F}(N_{Step}, k) = \frac{R(N_{Step}^k, k)}{N_{Step}^k} \sum_{\mu=1}^{N_{Step}^k} F_\mu^k \quad (1.6)$$

$$R(N_{step}^k, k) = \begin{cases} N_{full}, & N_{step}^k < N_{full} \\ 1, & N_{step}^k \geq N_{full} \end{cases} \quad (1.7)$$

with the linear ramp function $R(N_{step}^k, k)$ preventing large fluctuations of the force estimate at the beginning of the simulation from driving the system away from equilibrium. The

number of samples when the full biasing force is applied, N_{full} , and the bin size are the only free parameters that have to be chosen by the user before the simulation. For a sufficiently large number of samples N_{step}^k equation 1.6 approaches the correct average force in each bin and the free energy difference ΔA can be estimated by the numerically integrating over the force estimates in individual bins:^[3]

$$\Delta A_\xi = - \sum_{k=1}^M \overline{F}(N_{Step}, k) \delta \xi \quad (1.8)$$

The last missing ingredient for the ABF method is an explicit expression for the instantaneous force F_ξ . Carter et al.^[6] gave a first general expression:

$$F(\xi, \mathbf{q}) = - \frac{\partial V(\xi, \mathbf{q})}{\partial \xi} + \beta^{-1} \frac{\partial \ln |J(\xi, \mathbf{q})|}{\partial \xi} \quad (1.9)$$

which depends implicitly on a vector field $\partial x_i / \partial \xi$, hereafter referred to as "inverse gradient" and on an Jacobian correction term purely geometric in origin. The inverse gradient can be thought of as direction along which an infinitesimal change in ξ is propagated in Cartesian coordinates, the complementary coordinates \mathbf{q} being kept constant. A major drawback of this formalism is the requirement of an full coordinate transform from Cartesian coordinates (\mathbf{x}) to generalized coordinates (ξ, \mathbf{q}) .

This requirement could be lifted by den Otter,^[7] who put forward the breakthrough idea that the change in ξ can be propagated along an arbitrary vector field \mathbf{v}_i ($\mathbb{R}^{3N} \rightarrow \mathbb{R}^{3N}$), provided it satisfies some orthonormality conditions. Extended to multidimensional reaction coordinates $\xi = (\xi_i)$ and in presence of a set of constraints $\sigma_k(\mathbf{x}) = 0$ these read:^[8]

$$\mathbf{v}_i \cdot \nabla \xi_j = \delta_{ij} \quad (1.10)$$

$$\mathbf{v}_i \cdot \nabla \sigma_k = 0 \quad (1.11)$$

If all reaction coordinates ξ_i are orthogonal to one another and to all constraints, $\mathbf{v}_i = \nabla \xi_j / |\nabla \xi_j|^2$ is always a valid option. Otherwise conditions 1.10 and 1.11 can be fulfilled by orthogonalization:^[8]

$$v_i(\mathbf{x}) = \frac{Q^i \nabla \xi_i(\mathbf{x})}{|Q^i \nabla \xi_i(\mathbf{x})|} \quad (1.12)$$

with projector Q^i given by the orthonormal basis $\{\hat{n}_j^i(\mathbf{x})\}_{j \neq i}$ in the subspace spanned by

$$\{\nabla \xi_j(\mathbf{x})\}_{j \neq i} \cup \{\nabla \sigma_j(\mathbf{x})\}_{j=1,\dots,M}:$$

$$Q^i = \mathbf{1} - \sum_{j \neq i} \hat{n}_j^i(\mathbf{x}) \otimes \hat{n}_j^i(\mathbf{x}) \quad (1.13)$$

Replacing the inverse gradient by vectorfield \mathbf{v}_i , expression 1.9 finally reduces to:

$$F(\xi_i, \mathbf{x}) = -\nabla V(\mathbf{x}) \cdot \mathbf{v}_i(\mathbf{x}) + \beta^{-1} \nabla \cdot \mathbf{v}_i(\mathbf{x}) \quad (1.14)$$

but still involves the calculation of second derivatives in the form of the divergence of vector fields \mathbf{v}_i .^[3] Analytic expressions for bend angles and torsion angles, used in the present work, are given in the appendix. However, especially for torsion angles orthogonalization via equation 1.12 becomes exceedingly tedious and impractical, significantly limiting the applicability of ABF for multidimensional reaction coordinates.

1.3.3 extended Adaptive Biasing Force Method (eABF)

To circumvent the technical requirements of ABF for collective variables, namely being orthogonal to one-another and to constraints, Lesage et al.^[9] proposed an more flexible approach named eABF. In eABF the physical system is extended by additional coordinates λ with mass m_λ , which are coupled to the reaction coordinates ξ_i with harmonic potentials. The extended system (\mathbf{x}, λ) evolves according to Langevin dynamics in the extended potential

$$V^{ext}(\mathbf{x}, \lambda_i) = V(\mathbf{x}) + \frac{k_i}{2} (\xi_i(\mathbf{x}) - \lambda_i)^2. \quad (1.15)$$

The key intuition behind eABF is, that in the tight coupling limit efficient sampling of λ will result in efficient sampling of ξ . Therefore, to obtain uniform sampling along ξ biasing of λ is sufficient. The inverse gradient is chosen as null for all physical coordinates (\mathbf{x}) and 1 for λ . This way constraints 1.10 and 1.11 are always satisfied, which is especially useful for calculations involving a set of non-orthogonal reaction coordinates. Sampling the extended system gives the following unbiased Boltzmann distribution in λ :

$$\begin{aligned} \rho^k(\lambda) &\propto \int \exp \left[-\beta \left(V(\mathbf{x}) + \frac{k}{2} (\xi(\mathbf{x}) - \lambda)^2 \right) \right] d\mathbf{x} \\ &= \int \exp \left[-\beta V(\mathbf{x}) - \frac{(\xi(\mathbf{x}) - \lambda)^2}{2\sigma^2} \right] d\mathbf{x} \end{aligned} \quad (1.16)$$

which depends on the force constant k or variance of the Gaussian kernel $\sigma^2 = (\beta k)^{-1}$. The bias on λ is the running average over the spring force in λ -bin k :

$$\bar{F}(\lambda_i, k) = \frac{\partial A^k(\lambda_i)}{\partial \lambda_i} = \frac{1}{N_{Step}^k} \sum_{\mu=1}^{N_{Step}^k} k(\lambda_{i,\mu}^k - \xi_{i,\mu}^k) \quad (1.17)$$

For small values of N_{Step}^k again the linear ramp function $R(N_{Step}, k)$ given by equation 1.7 is used. This generates the following biased Boltzmann distribution:

$$\tilde{\rho}(\lambda) \propto \int \exp \left[-\beta V(\mathbf{x}) - \frac{(\xi(\mathbf{x}) - \lambda)^2}{2\sigma^2} + A^k(\lambda) \right] d\mathbf{x} \quad (1.18)$$

By using $\int \delta(\xi(\mathbf{x}) - z) dz = 1$ and $A^k(\lambda) = -\beta^{-1} \ln \rho^k(\lambda)$ one can obtain the relationship between unbiased and biased z -distributions:

$$\tilde{\rho}(z) = \rho(z) \int \frac{\exp\left(-\frac{(\lambda-z)^2}{2\sigma^2}\right)}{\int \exp\left(-\frac{(\lambda-z')^2}{2\sigma^2}\right) \rho(z') dz'} d\lambda \quad (1.19)$$

For the tight coupling limit (high k , low σ) the unbiased distribution $\rho(z)$ is recovered and eABF recovers the behavior of standard ABF. In this case $A^k(\lambda)$ approximates the physical free energy $A(z)$ and the ΔA_z can be approximated by integrating over the converged bias forces on λ , $\bar{F}(\lambda_i, k)$, which will be referred to as "naive estimator" (eABF/naive) hereafter.

An asymptotically unbiased estimator of the free energy can be derived by correcting the free energy gradient obtained from the eABF-biased distribution $\tilde{\rho}(z)$ with the average biasing force on z

$$\frac{\partial A(z)}{\partial z_i} = -\beta^{-1} \frac{\partial \ln \tilde{\rho}(z)}{\partial z_i} + k(\langle \lambda_i \rangle_z - z_i) \quad (1.20)$$

which is called "Corrected z -averaged restraint" (CZAR) and can be calculated numerically from the time trajectory (z_i, λ_i) in an post-processing step.^[9]

1.3.4 Meta-eABF

2 Appendix

2.1 Reaction coordinates

In the present work valance angles and torsion angles were used as collective variables for Umbrella Sampling, metaD, ABF, eABF or meta-eABF simulations. Below analytic expressions for the calculation of both variables, their gradients, inverse gradients and divergence of inverse gradients are given.

2.1.1 Bond Angle

The bond angle θ between three Cartesian coordinates (r_1, r_2, r_3) is given by the dot product between bond distances $r_{ij} = r_j - r_i$:

$$\cos \theta = \hat{r}_{21} \cdot \hat{r}_{23} \quad (2.1)$$

The derivative of θ in Cartesian coordinates is then given by

$$\frac{\partial \theta}{\partial r_1} = \frac{\text{norm}(\hat{r}_{21} \times (\hat{r}_{21} \times \hat{r}_{23}))}{|r_{12}|} \quad (2.2)$$

$$\frac{\partial \theta}{\partial r_3} = \frac{\text{norm}(\hat{r}_{32} \times (\hat{r}_{21} \times \hat{r}_{23}))}{|r_{23}|} \quad (2.3)$$

$$\frac{\partial \theta}{\partial r_2} = -\frac{\partial \theta}{\partial r_1} - \frac{\partial \theta}{\partial r_3} \quad (2.4)$$

Choosing as inverse gradient $\mathbf{v}_i = \nabla \theta / |\nabla \theta|^2$ the divergence of vector field \mathbf{v}_i is given by:

$$\nabla \cdot \mathbf{v}_i = \cot \theta \quad (2.5)$$

2.1.2 Torsion Angle

The torsion angle ϕ between four Cartesian coordinates (r_1, r_2, r_3, r_4) is given by:

$$\tan \phi = \frac{(\hat{r}_{12} \times n_1) \cdot n_2}{n_1 \cdot n_2} \quad (2.6)$$

with

$$n_1 = r_{23} - (r_{12} \cdot \hat{r}_{23})\hat{r}_{23} \quad (2.7)$$

$$n_2 = r_{34} - (r_{34} \cdot \hat{r}_{23})\hat{r}_{23} \quad (2.8)$$

The derivative of ϕ in Cartesian coordinates is given by:

$$\frac{\partial \phi}{\partial r_1} = -\frac{\hat{r}_{21} \times \hat{r}_{23}}{|r_{12}| \sin^2 \theta_{123}} \quad (2.9)$$

$$\frac{\partial \phi}{\partial r_4} = -\frac{\hat{r}_{34} \times \hat{r}_{23}}{|r_{34}| \sin^2 \theta_{234}} \quad (2.10)$$

$$\frac{\partial \phi}{\partial r_2} = c_{123} \frac{\partial \phi}{\partial r_1} - b_{432} \frac{\partial \phi}{\partial r_4} \quad (2.11)$$

$$\frac{\partial \phi}{\partial r_3} = -\frac{\partial \phi}{\partial r_1} - \frac{\partial \phi}{\partial r_4} - \frac{\partial \phi}{\partial r_2} \quad (2.12)$$

with

$$c_{123} = \frac{|r_{12}| \cos \theta_{123}}{|r_{23}|} - 1 \quad (2.13)$$

$$b_{432} = \frac{|r_{34}| \cos \theta_{234}}{|r_{23}|} \quad (2.14)$$

Choosing as inverse gradient $\mathbf{v}_i = \nabla \phi / |\nabla \phi|^2$ the divergence of vector field \mathbf{v}_i is zero:

$$\nabla \cdot \mathbf{v}_i = 0 \quad (2.15)$$
